

A Data-driven Approach to Robust Control of Multivariable Systems by Convex Optimization

Alireza Karimi¹ and Christoph Kammer

Laboratoire d'Automatique, École Polytechnique Fédérale de Lausanne (EPFL), CH-1015 Lausanne (Switzerland)

Abstract

The frequency-domain data of a multivariable system in different operating points is used to design a robust controller with respect to the measurement noise and multimodel uncertainty. The controller is fully parametrized in terms of matrix polynomial functions and can be formulated as a centralized, decentralized or distributed controller. All standard performance specifications like H_2 , H_∞ and loop shaping are considered in a unified framework for continuous- and discrete-time systems. The control problem is formulated as a convex-concave optimization problem and then convexified by linearization of the concave part around an initial controller. The performance criterion converges monotonically to a local optimum or a saddle point in an iterative algorithm. The effectiveness of the method is compared with fixed-structure controller design methods based on non-smooth optimization via multiple simulation examples.

Key words: Data-driven control, robust control, convex optimization

1 Introduction

Recent developments in the fields of numerical optimization, computer and sensor technology have led to a significant reduction of the computational time of optimization algorithms and have increased the availability of large amounts of measured data during a system's operation. These progresses make computationally demanding data-driven control design approaches an interesting alternative to the classical model-based control problems. In these approaches, the controller parameters are directly computed by minimizing a control criterion which is a function of measured data. Therefore, a parametric model of the plant is not required and there are no unmodeled dynamics. The only source of uncertainty is the measurement noise, whose influence can be reduced significantly if the amount of measurement data is large.

Frequency-domain data is used in the classical loop-shaping methods for computing simple lead-lag or PID controllers for SISO stable plants. The Quantitative Feedback Theory (QFT) uses also the frequency response of the plant model to compute robust controllers (Horowitz, 1993). In these approaches the controller parameters are tuned manually using graphical methods. New optimization-based algorithms have also been proposed recently (Mercader *et al.*, 2016). The set of all stabilizing PID controllers with H_∞ performance is obtained using only the frequency-domain data in Keel and Bhattacharyya (2008). This method is extended to design of fixed-order linearly parameterized controllers in Parast-

vand and Khosrowjerdi (2015, 2016). The frequency response data are used in Hoogendijk *et al.* (2010) to compute the frequency response of a controller that achieves a desired closed-loop pole location. A data-driven synthesis methodology for fixed structure controller design problems with H_∞ performance is presented in Den Hamer *et al.* (2009). This method uses the Q parameterization in the frequency domain and solves a non-convex optimization problem to find a local optimum. Another frequency-domain approach is presented in Khadraoui *et al.* (2013) to design reduced order controllers with guaranteed bounded error on the difference between the desired and achieved magnitude of sensitivity functions. This approach also uses a non-convex optimization method.

Another direction for robust controller design based on frequency-domain data is the use of convex optimization methods. A linear programming approach is used to compute linearly parametrized (LP) controllers for SISO systems with specifications in gain and phase margin as well as the desired closed-loop bandwidth in Karimi *et al.* (2007); Saeki (2014). A convex optimization approach is used to design LP controllers with loop shaping and H_∞ performance in Karimi and Galdos (2010). This method is extended to MIMO systems for computing decoupling LP-MIMO controllers in Galdos *et al.* (2010). Recently, the necessary and sufficient conditions for the existence of data-driven H_∞ controllers for SISO systems has been proposed in Karimi *et al.* (2016).

The use of the frequency response for computing SISO-PID controllers by convex optimization is proposed in Hast *et al.* (2013). This method uses the same type of

¹ Corresponding author: alireza.karimi@epfl.ch

linearization of the constraints as in Karimi and Galdos (2010) but interprets it as a convex-concave approximation technique. An extension of Hast *et al.* (2013) for the design of MIMO-PID controllers by linearization of quadratic matrix inequalities is proposed in Boyd *et al.* (2016) for stable plants. A similar approach, with the same type of linearization, is used in Saeki *et al.* (2010) for designing LP-MIMO controllers (which includes PID controllers as a special case). This approach is not limited to stable plants and includes the conditions for the stability of the closed-loop system.

In this paper, a new data-driven controller design approach is proposed based on the frequency response of multivariable systems and convex optimization. Contrarily to the existing results in Galdos *et al.* (2010); Boyd *et al.* (2016); Saeki *et al.* (2010), the controller is fully parameterized and the design is not restricted to LP or PID controllers. The other contribution is that the control specification is not limited to H_∞ performance. The H_2 , H_∞ and mixed H_2/H_∞ control problem as well as loop shaping in two- and infinity-norm are presented in a unified framework for systems with multimodel uncertainty. A new closed-loop stability proof based on the Nyquist stability criterion is also given.

It should be mentioned that the problem is convexified using the same type of approximation as the one used in Boyd *et al.* (2016); Saeki *et al.* (2010). Therefore, like other fixed-structure controller design methods (model-based or data-driven), the results are local and depend on the initialization of the algorithm.

2 Preliminaries

The system to be controlled is a Linear Time-Invariant Multi-Input Multi-Output (LTI-MIMO) system represented by a multivariable frequency response model $G(e^{j\omega}) \in \mathbb{C}^{n \times m}$, where n is the number of outputs and m the number of inputs. The frequency response model can be identified using the Fourier analysis method from m sets of input/output sampled data as (Pintelon and Schoukens, 2001):

$$G(e^{j\omega}) = \left[\sum_{k=0}^{N-1} y(k) e^{-j\omega T_s k} \right] \left[\sum_{k=0}^{N-1} u(k) e^{-j\omega T_s k} \right]^{-1} \quad (1)$$

where N is the number of data points for each experiment, $u(k) \in \mathbb{R}^{m \times m}$ includes the inputs at instant k , $y(k) \in \mathbb{R}^{n \times m}$ the outputs at instant k and T_s is the sampling period. Note that at least m different experiments are needed to extract G from the data (each column of $u(k)$ and $y(k)$ represents respectively the input and the output data from one experiment). We assume that $G(e^{j\omega})$ is bounded in all frequencies except for a set B_g including a finite number of frequencies that correspond to the poles of G on the unit circle. Since the frequency function $G(e^{j\omega})$ is periodic, we consider:

$$\omega \in \Omega_g = \left\{ \omega \left| -\frac{\pi}{T_s} \leq \omega \leq \frac{\pi}{T_s} \right. \right\} \setminus B_g \quad (2)$$

A fixed-structure matrix transfer function controller is considered. The controller is defined as $K = XY^{-1}$, where X and Y are polynomial matrices in s for continuous-time or in z for discrete-time controller design. This controller structure, therefore, can be used for both continuous-time or discrete-time controllers. The matrix X has the following structure:

$$X = \begin{bmatrix} X_{11} & \dots & X_{1n} \\ \vdots & \ddots & \vdots \\ X_{m1} & \dots & X_{mn} \end{bmatrix} \circ F_x \quad (3)$$

where X and F_x are $m \times n$ polynomial matrices and \circ denotes the element by element multiplication of matrices. The matrix F_x represents the fixed known terms in the controller that are designed to have specific performance, e.g. based on the internal model principle. For discrete-time controllers, we have:

$$X(z) = X_p z^p + \dots + X_1 z + X_0 \quad (4)$$

where $X_i \in \mathbb{R}^{m \times n}$ for $i = 0, \dots, p$ contain the controller parameters. In the same way the matrix polynomial Y can be defined as:

$$Y = \begin{bmatrix} Y_{11} & \dots & Y_{1n} \\ \vdots & \ddots & \vdots \\ Y_{n1} & \dots & Y_{nn} \end{bmatrix} \circ F_y \quad (5)$$

where Y and F_y are $n \times n$ polynomial matrices. The matrix F_y represents the fixed terms of the controller, e.g. integrators or the denominator of other disturbance models. The set of frequencies of all roots of the determinant of F_y on the stability boundary (imaginary axis for continuous-time controllers or the unit circle for the discrete-time case) is denoted by B_y .

The matrix Y for discrete-time case can be written as:

$$Y(z) = I z^p + \dots + Y_1 z + Y_0 \quad (6)$$

where $Y_i \in \mathbb{R}^{n \times n}$ for $i = 0, \dots, p-1$ contain the controller parameters. In order to obtain low-order controllers, a diagonal structure can be considered for Y that makes its inversion and implementation easier too. Note that $Y(e^{j\omega})$ should be invertible for all $\omega \in \Omega = \Omega_g \setminus B_y$.

The control structure defined in this section is very general and covers centralized, decentralized and distributed control structures. The well-known PID control structure for MIMO systems is also a special case of this structure.

3 Control Performance

It is shown in this section that classical control performance constraints can be transformed to constraints on

the spectral norm of the system and in general can be reformulated as:

$$F^*F - P^*P < \gamma I \quad (7)$$

where $F \in \mathbb{C}^{n \times n}$ and $P \in \mathbb{C}^{n \times n}$ are linear in the optimization variables and $(\cdot)^*$ denotes the complex conjugate transpose. This type of constraint is called convex-concave constraint and can be convexified using the Taylor expansion of P^*P around $P_c \in \mathbb{C}^{n \times n}$ which is an arbitrary known matrix (Dinh *et al.*, 2012):

$$P^*P \approx P_c^*P_c + (P - P_c)^*P_c + P_c^*(P - P_c) \quad (8)$$

It is easy to show that the left hand side term is always greater than or equal to the right hand side term, i.e. :

$$P^*P \geq P^*P_c + P_c^*P - P_c^*P_c \quad (9)$$

This can be obtained easily by development of the inequality $(P - P_c)^*(P - P_c) \geq 0$.

3.1 H_∞ performance

Constraints on the infinity-norm of any weighted sensitivity function can be considered. For example, consider the mixed sensitivity problem:

$$\min_K \left\| \begin{bmatrix} W_1 S \\ W_2 K S \end{bmatrix} \right\|_\infty \quad (10)$$

where $S = (I + GK)^{-1}$ is the sensitivity function, W_1 is the performance weight and W_2 is the input weight. This problem can be converted to an optimization problem on the spectral norm as:

$$\begin{aligned} & \min_K \gamma \\ & \text{subject to:} \\ & \begin{bmatrix} W_1 S \\ W_2 K S \end{bmatrix}^* \begin{bmatrix} W_1 S \\ W_2 K S \end{bmatrix} < \gamma I, \quad \forall \omega \in \Omega \end{aligned} \quad (11)$$

Note that the argument $e^{j\omega}$ has been omitted for $W_1(e^{j\omega})$, $S(e^{j\omega})$, $K(e^{j\omega})$ and $W_2(e^{j\omega})$ in order to simplify the notation. The above constraint can be rewritten as:

$$\begin{aligned} & [W_1(I + GK)^{-1}]^* [W_1(I + GK)^{-1}] + \\ & [W_2 K(I + GK)^{-1}]^* [W_2 K(I + GK)^{-1}] < \gamma I \end{aligned} \quad (12)$$

and converted to a convex-concave constraint as follows:

$$\begin{aligned} & Y^* W_1^* \gamma^{-1} W_1 Y + X^* W_2^* \gamma^{-1} W_2 X \\ & - (Y + GX)^*(Y + GX) < 0 \end{aligned} \quad (13)$$

If we denote $P = Y + GX$, using (9), a convex approximation of the constraint can be obtained around $P_c = Y_c + GX_c$ as:

$$\begin{aligned} & Y^* W_1^* \gamma^{-1} W_1 Y + X^* W_2^* \gamma^{-1} W_2 X \\ & - P^* P_c - P_c^* P + P_c^* P_c < 0 \end{aligned} \quad (14)$$

Therefore, using the Schur complement lemma, the H_∞ mixed sensitivity problem can be represented as the following convex optimization problem with linear matrix inequalities (LMIs):

$$\begin{aligned} & \min_{X,Y} \gamma \\ & \text{subject to:} \\ & \begin{bmatrix} P^* P_c + P_c^* P - P_c^* P_c & (W_1 Y)^* & (W_2 X)^* \\ W_1 Y & \gamma I & 0 \\ W_2 X & 0 & \gamma I \end{bmatrix} > 0 \end{aligned} \quad (15)$$

for all $\omega \in \Omega$. This convex constraint is a sufficient condition for the spectral constraint in (11) for any choice of an initial controller $K_c = X_c Y_c^{-1}$.

3.2 H_2 performance

In this section, we show how the H_2 control performance can be formulated as a convex optimization problem. We consider the following H_2 control performance:

$$\min_K \|W_1 S\|_2^2 \quad (16)$$

For a stable closed-loop system, this is equivalent to:

$$\min_K \int_{-\frac{\pi}{T_s}}^{\frac{\pi}{T_s}} \text{trace}[\Gamma(\omega)] d\omega \quad (17)$$

subject to:

$$W_1 [(I + GK)^*(I + GK)]^{-1} W_1^* < \Gamma(\omega) \quad \forall \omega \in \Omega$$

where $\Gamma(\omega) > 0$ is an unknown matrix function $\in \mathbb{R}^{n \times n}$. Replacing K with XY^{-1} , we obtain:

$$W_1 Y [(Y + GX)^*(Y + GX)]^{-1} Y^* W_1^* < \Gamma(\omega) \quad \forall \omega \in \Omega$$

which is equivalent to the following matrix inequality:

$$\begin{bmatrix} \Gamma(\omega) & W_1 Y \\ Y^* W_1^* & (Y + GX)^*(Y + GX) \end{bmatrix} > 0, \quad \forall \omega \in \Omega \quad (18)$$

The quadratic part can be linearized using (9) to obtain a linear matrix inequality as:

$$\begin{bmatrix} \Gamma(\omega) & W_1 Y \\ Y^* W_1^* & P^* P_c + P_c^* P - P_c^* P_c \end{bmatrix} > 0, \quad \forall \omega \in \Omega \quad (19)$$

Remark: The unknown function $\Gamma(\omega)$ can be approximated by a polynomial function of finite order as:

$$\Gamma(\omega) = \Gamma_0 + \Gamma_1 \omega + \dots + \Gamma_h \omega^h \quad (20)$$

In case the constraints are evaluated for a finite set of frequencies $\Omega_N = \{\omega_1, \dots, \omega_N\}$, $\Gamma(\omega)$ can be replaced with a matrix variable Γ_k at each frequency ω_k .

3.3 Loop shaping

Assume that a desired loop transfer function L_d is available and that the objective is to design a controller K such that the loop transfer function $L = GK$ is close to L_d in the 2- or ∞ -norm sense. The objective function for the ∞ -norm case is to minimize $\|L - L_d\|_\infty$ and can be expressed as follows:

$$\begin{aligned} & \min_K \gamma \\ & \text{subject to:} \\ & (GK - L_d)^*(GK - L_d) < \gamma I \quad \forall \omega \in \Omega \end{aligned} \quad (21)$$

Replacing K with XY^{-1} in the constraint, we obtain:

$$(GX - L_dY)^*\gamma^{-1}(GX - L_dY) - Y^*Y < 0 \quad (22)$$

Again Y^*Y can be linearized around Y_c using the linear approximation in (9). Thus, the following convex formulation is obtained:

$$\begin{aligned} & \min_{X,Y} \gamma \\ & \text{subject to:} \\ & \begin{bmatrix} Y^*Y_c + Y_c^*Y - Y_c^*Y_c & (GX - L_dY)^* \\ GX - L_dY & \gamma I \end{bmatrix} > 0 \end{aligned} \quad (23)$$

for all $\omega \in \Omega$. In a similar way, for minimizing $\|L - L_d\|_2^2$ the following convex optimization problem can be solved:

$$\begin{aligned} & \min_{X,Y} \int_{-\frac{\pi}{T_s}}^{\frac{\pi}{T_s}} \text{trace}[\Gamma(\omega)] d\omega \\ & \text{subject to:} \\ & \begin{bmatrix} Y^*Y_c + Y_c^*Y - Y_c^*Y_c & (GX - L_dY)^* \\ GX - L_dY & \Gamma(\omega) \end{bmatrix} > 0 \end{aligned} \quad (24)$$

for all $\omega \in \Omega$. Note that the resulting loop shaping controller does not necessarily guarantee the closed-loop stability. This will be discussed in the next section, where the stability conditions will be developed.

4 Robust Controller Design

4.1 Stability analysis

The stability of the closed-loop system is not necessarily guaranteed even if the spectral norm of a weighted sensitivity function is bounded. In fact, an unstable system with no pole on the stability boundary has a bounded spectral norm. In this section, we show that the closed-loop stability can be guaranteed if some conditions in the linearization of the constraints are met. More precisely, the initial controller $K_c = X_c Y_c^{-1}$ plays an important role in guaranteeing the stability of the closed-loop system with the resulting controller K . Our stability analysis is based on the generalized Nyquist stability criterion for MIMO systems that is recalled here for discrete-time

systems. Note that the results are also straightforwardly applicable to the continuous-time case by modifying the Nyquist contour.

Theorem 1 (Nyquist stability theorem) *The closed-loop system with the plant model $G(z)$ and the controller $K(z)$ is stable if and only if the Nyquist plot of $\det(I + G(z)K(z))$*

- (1) *makes $N_G + N_K$ counterclockwise encirclements of the origin, where N_G and N_K are, respectively, the number of poles of $G(z)$ and $K(z)$ on the exterior of the unit circle, and*
- (2) *does not pass through the origin.*

The Nyquist plot is the image of $\det(I + GK)$ as z traverses the Nyquist contour (the unit circle) counterclockwise. We assume that the Nyquist contour has some small detours around the poles of $G(z)$ and $K(z)$ on the unit circle.

Definition 1 *Let $\text{wno}\{F(z)\}$ be the winding number, in the counterclockwise sense, of the image of $F(z)$ around the origin when z traverses the Nyquist contour with some small detours around the poles of $F(z)$ on the unit circle.*

Since the winding number is related to the phase of the complex function, we have the following properties:

$$\text{wno}\{F_1(z)F_2(z)\} = \text{wno}\{F_1(z)\} + \text{wno}\{F_2(z)\} \quad (25)$$

$$\text{wno}\{F(z)\} = -\text{wno}\{F^*(z)\} \quad (26)$$

$$\text{wno}\{F(z)\} = -\text{wno}\{F^{-1}(z)\} \quad (27)$$

Theorem 2 *Given a plant model G , an initial stabilizing controller $K_c = X_c Y_c^{-1}$ with $\det(Y_c) \neq 0, \forall \omega \in \Omega$, and feasible solutions X and Y to the following LMI,*

$$(Y + GX)^*(Y_c + GX_c) + (Y_c + GX_c)^*(Y + GX) > 0 \quad (28)$$

for all $\omega \in \Omega$, then the controller $K = XY^{-1}$ stabilizes the closed-loop system if

- (1) $\det(Y) \neq 0, \forall \omega \in \Omega$.
- (2) *The initial controller K_c and the final controller K share the same poles on the stability boundary, i.e. $\det(Y) = \det(Y_c) = 0, \forall \omega \in B_y$.*
- (3) *The order of $\det(Y)$ is equal to the order of $\det(Y_c)$.*

Remark: Note that the condition in (28) is always met when a convexified H_∞ or H_2 control problem has a feasible solution because we have $P^*P_c + P_c^*P > 0$ in (15) and (19).

Proof: The proof is based on the Nyquist stability criterion and the properties of the winding number. The wind-

ing number of the determinant of $P^*(z)P_c(z)$ is given by:

$$\begin{aligned} \text{wno}\{\det(P^*P_c)\} &= \text{wno}\{\det(P^*)\} + \text{wno}\{\det(P_c)\} \\ &= -\text{wno}\{\det(I + GK)\det(Y)\} \\ &\quad + \text{wno}\{\det(I + GK_c)\det(Y_c)\} \\ &= -\text{wno}\{\det(I + GK)\} \\ &\quad - \text{wno}\{\det(Y)\} + \text{wno}\{\det(Y_c)\} \\ &\quad + \text{wno}\{\det(I + GK_c)\} \end{aligned} \quad (29)$$

Note that the phase variation of $\det(P^*P_c)$ for the small detour in the Nyquist contour is zero, if Condition 2 of the theorem is satisfied. In fact for each small detour, the Nyquist plot of $\det(I + GK)$ and $\det(I + GK_c)$ will have the same phase variation because K and K_c share the same poles on the unit circle. As a result, the winding number of $\det(P^*P_c)$ can be evaluated on Ω instead of the Nyquist contour. On the other hand, the condition in (28) implies that $P^*(e^{j\omega})P_c(e^{j\omega})$ is a non-Hermitian positive definite matrix in the sense that :

$$\Re\{x^*P^*(e^{j\omega})P_c(e^{j\omega})x\} > 0 \quad \forall x \neq 0 \in \mathbb{C}^n \quad (30)$$

and $\forall \omega \in \Omega$. This, in turn, means that all eigenvalues of $P^*(e^{j\omega})P_c(e^{j\omega})$, denoted $\lambda_i(\omega)$ for $i = 1, \dots, n$, have positive real parts at all frequencies (Zhang *et al.*, 2010):

$$\Re\{\lambda_i(\omega)\} > 0 \quad \forall \omega \in \Omega, i = 1, \dots, n \quad (31)$$

Therefore, $\lambda_i(\omega)$ will not pass through the origin and not encircle it (i.e. its winding number is zero). As a result, since the determinant of a matrix is the product of its eigenvalues, we have:

$$\text{wno}\{\det(P^*P_c)\} = \text{wno}\left\{\prod_{i=1}^n \lambda_i\right\} = \sum_{i=1}^n \text{wno}\{\lambda_i\} = 0$$

Since K_c is a stabilizing controller, based on the Nyquist theorem $\text{wno}\{\det(I + GK_c)\} = N_G + N_{K_c}$. Furthermore, according to the argument principle $\text{wno}\{\det(Y)\} = \delta - N_K$ and $\text{wno}\{\det(Y_c)\} = \delta - N_{K_c}$, where δ is the order of $\det(Y)$ and $\det(Y_c)$ according to Condition 3. Now using (29), we obtain:

$$\begin{aligned} \text{wno}\{\det(I + GK)\} &= \text{wno}\{\det(I + GK_c)\} \\ &\quad - \text{wno}\{\det(Y)\} + \text{wno}\{\det(Y_c)\} \\ &= N_G + N_K \end{aligned} \quad (32)$$

which shows that Condition 1 of the Nyquist theorem is met. Moreover, we can see from (31) that

$$\det(P^*P_c) = \prod_{i=1}^n \lambda_i(\omega) \neq 0 \quad \forall \omega \in \Omega \quad (33)$$

Therefore, $\det(P) = \det(I + GK)\det(Y) \neq 0$ and the Nyquist plot of $\det(I + GK)$ does not pass through the origin and Condition 2 of the Nyquist theorem is also satisfied. ■

Remark 1: A necessary and sufficient condition for $\det(Y) \neq 0$ is $Y^*Y > 0$. Since this constraint is concave,

it can be linearized to obtain the following sufficient LMI:

$$Y^*Y_c + Y_c^*Y - Y_c^*Y_c > 0 \quad (34)$$

This constraint can be added to the optimization problem in (15) in order to guarantee the closed-loop stability for the mixed sensitivity problem. For the loop-shaping problems in (23) and in (24), this condition is already included in the formulation. Therefore, for guaranteeing the closed-loop stability, the condition in (28) should be added. This condition can be added directly or by considering an additional H_2 or H_∞ constraint on a closed-loop sensitivity function.

Remark 2: In practice, condition 3 of Theorem 2 is not restrictive. Any initial controller of lower order than the final controller can be augmented by adding an appropriate number of zeros and poles at the origin in X and Y , thus satisfying the condition without affecting the initial controller.

4.2 Multimodel uncertainty

The case of robust control design with multimodel uncertainty is very easy to incorporate in the given framework. Systems that have different frequency responses in q different operating points can be represented by a multimodel uncertainty set:

$$\mathcal{G}(e^{j\omega}) = \{G_1(e^{j\omega}), G_2(e^{j\omega}), \dots, G_q(e^{j\omega})\} \quad (35)$$

Note that the models may have different orders and may contain the pure input/output time delay.

This can be implemented by formulating a different set of constraints for each of the models. Let $P_i = Y + G_iX$ and $P_{c_i} = X_c + G_iY_c$. Again taking the mixed sensitivity problem as an example, the formulation of this problem including the stability constraint would be:

$$\begin{aligned} &\min_{X,Y} \gamma \\ &\text{subject to:} \\ &\left[\begin{array}{ccc} P_i^*P_{c_i} + P_{c_i}^*P_i - P_{c_i}^*P_{c_i} & (W_1Y)^* & (W_2X)^* \\ W_1Y & \gamma I & 0 \\ W_2X & 0 & \gamma I \end{array} \right] > 0 \\ &Y^*Y_c + Y_c^*Y - Y_c^*Y_c > 0 \\ &\text{for } i = 1, \dots, q \quad ; \quad \forall \omega \in \Omega \end{aligned} \quad (36)$$

4.3 Frequency-domain uncertainty

The frequency function may be affected by the measurement noise. In this case, the model uncertainty can be represented as :

$$\tilde{G}(e^{j\omega}) = G(e^{j\omega}) + W_1(e^{j\omega})\Delta W_2(e^{j\omega}) \quad (37)$$

where Δ is the unit ball of matrices of appropriate dimension and $W_1(e^{j\omega})$ and $W_2(e^{j\omega})$ are known complex matrices that specify the magnitude of and directional information about the measurement noise. A convex optimization approach is proposed in Hindi *et al.* (2002) to compute the optimal uncertainty filters from the frequency-domain data. The system identification toolbox of Matlab provides the variance of $G_{ij}(e^{j\omega})$ (the frequency function between the i -th output and the j -th input) from the estimates of the noise variance that can be used for computing W_1 and W_2 .

The robust stability condition for this type of uncertainty is (Zhou, 1998): $\|W_2 K S W_1\|_\infty < 1$. If we assume that $W_1(e^{j\omega})$ is invertible for all $\omega \in \Omega$ (i.e. it has no pole on the unit circle), then a set of robustly stabilizing controllers can be given by the following spectral constraints:

$$\begin{bmatrix} P^*P_c + P_c^*P - P_c^*P_c (W_2X)^* \\ W_2X & I \end{bmatrix} > 0 \quad (38)$$

$$Y^*Y_c + Y_c^*Y - Y_c^*Y_c > 0 \quad ; \quad \forall \omega \in \Omega$$

where $P = W_1^{-1}(Y + GX)$ and $P_c = W_1^{-1}(Y_c + GX_c)$.

5 Implementation Issues

5.1 Frequency gridding

The optimization problems formulated in this paper contain an infinite number of constraints (i.e. $\forall \omega \in \Omega$) and are called semi-infinite problems. A common approach to handle this type of constraints is to choose a reasonably large set of frequency samples $\Omega_N = \{\omega_1, \dots, \omega_N\}$ and replace the constraints with a finite set of constraints at each of the given frequencies. As the complexity of the problem scales linearly with the number of constraints, N can be chosen relatively large without severely impacting the solver time. The frequency range $[0, \pi/T_s]$ is usually gridded logarithmically-spaced. Since all constraints are applied to Hermitian matrices, the constraints for the negative frequencies between $-\pi/T_s$ and zero will be automatically satisfied. In some applications with low-damped resonance frequencies, the density of the frequency points can be increased around the resonant frequencies. An alternative is to use a randomized approach for the choice of the frequencies at which the constraints are evaluated (Alamo *et al.*, 2010).

Taking the mixed sensitivity problem as an example, the sampled problem would be:

$$\begin{aligned} & \min_{X,Y} \gamma \\ & \text{subject to:} \\ & \begin{bmatrix} P^*P_c + P_c^*P - P_c^*P_c (W_1Y)^* (W_2X)^* \\ W_1Y & \gamma I & 0 \\ W_2X & 0 & \gamma I \end{bmatrix} (e^{j\omega}) > 0 \\ & [Y^*Y_c + Y_c^*Y - Y_c^*Y_c] (e^{j\omega}) > 0 \quad ; \quad \omega \in \Omega_N \end{aligned} \quad (39)$$

5.2 Initial controller

The stability condition presented in Theorem 2 requires a stabilizing initial controller K_c with the same poles on the stability boundary (the unit circle) as the desired final controller. For a stable plant, a stabilizing initial controller can always be found by choosing:

$$[X_{c,1}, \dots, X_{c,p}] = 0, \quad X_{c,0} = \epsilon I \quad (40)$$

with ϵ being a sufficiently small number. Furthermore, the parameters of Y_c should be chosen such that $\det(Y_c) \neq 0$ for all $\omega \in \Omega$. This can be achieved by choosing Y_c such that all roots of $\det(Y_c) = 0$ lie at zero, with F_y containing all the poles on the unit circle of the desired final controller. For example, to design a controller with integral action in all outputs, $Y_c = z^p(z-1)I$ can be considered. Alternatively, if a working controller has already been implemented, it can be used as the initial controller.

When choosing an initial controller whose performance is far from the desired specifications, it may occur that either the optimization problem has no feasible solution, or that the solver runs into numerical problems which lead to an infeasible solution. These problems can often be resolved by two approaches:

Re-initialization: The initial controller can be changed with a systematic approach for stable plants by solving the following optimization problem using a nonlinear optimization solver with random initialization:

$$\begin{aligned} & \max_{X,Y} a \\ & \text{subject to:} \\ & \Re \{ \det(I + GXY^{-1}) \} \geq a \quad \forall \omega \in \Omega_N \end{aligned} \quad (41)$$

Any solution to the above optimization problem will be a stabilizing controller if the optimal value of a is greater than -1. The problem can be solved multiple times with different random initialization to generate a set of initial stabilizing controllers, which can be used to initialize the algorithm.

Relaxation: We can relax or even remove some of the constraints. The relaxed optimization problem is then solved and the optimal controller is used to initialize the non-relaxed problem. As this new controller is comparatively close to the final solution, the issue is often solved with this approach.

Since this work focuses on data-driven control design, for unstable plants it is reasonable to assume that a stabilizing controller has been available for data acquisition, and can thus be used as the initial controller.

It should be mentioned that the design of fixed-structure controllers in a model-based setting also requires an initialization with a stabilizing controller, which is usually integrated in the workflow. In the methods based on non-smooth optimization like *hinfstruct* in Matlab (Aparian and Noll, 2006) or the public-domain toolbox HIFOO (Burke *et al.*, 2006), the controllers are randomly initialized and maximum of the real part of the eigenvalues of a

closed-loop transfer function is minimized. The resulting stabilizing controllers are then used for the optimization of the objective function. Other model-based approaches use an initial stabilizing controller to convert the bilinear matrix inequalities to LMIs and solve it with convex optimization algorithms. Therefore, from this point of view, our data-driven approach is subject to the same restrictions as the state-of-the-art approaches for fixed-structure controller design in a model-based setting.

5.3 Iterative algorithm

Once a stabilizing initial controller is found, it is used to formulate the optimization problem. Any LMI solver can be used to solve the optimization problem and calculate a suboptimal controller K around the initial controller K_c . As we are only solving an inner convex approximation of the original optimization problem, K depends heavily on the initial controller K_c and the performance criterion can be quite far from the optimal value. The solution is to use an iterative approach that solves the optimization problem multiple times, using the final controller K of the previous step as the new initial controller K_c . This choice always guarantees closed-loop stability (assuming the initial choice of K_c is stabilizing). Since the objective function is non-negative and non-increasing, the iteration converges to a local optimum or a saddle point of the original non-convex problem (Yuille and Rangarajan, 2003). The iterative process can be stopped once the change in the performance criterion is sufficiently small.

6 Simulation Results

As an example, the mixed sensitivity problem for low-order continuous-time controllers is considered. 10 plants are drawn from the Compleib library (Leibfritz, 2006). For comparison, the achieved performance is compared with the results obtained using *hinfsstruct* and HIFOO. Parametric plant models are used in this example in order to enable comparison with state-of-the-art methods. However, it should be noted that, as our method is data-driven, only the frequency responses of the plants are required for the controller design.

The objective is to solve the mixed sensitivity problem by minimizing the infinity-norm of (10), where $W_2 = I$ and $W_1 = (a_k s + 10)/(a_k s + 1)$ with a_k being chosen based on the bandwidth of the plant. Then, the optimization problem in (39) is formed with $N = 100$ logarithmically spaced frequency points in the interval $[0.01, 500]$ rad/s, where 500 is much larger than the bandwidth of all plants. A second-order controller $K(s) = X(s)Y(s)^{-1}$ is chosen as follows:

$$X(s) = X_2 s^2 + X_1 s + X_0 \quad , \quad Y(s) = I s^2 + Y_1 s + Y_0$$

where Y_i is a diagonal matrix in order to obtain a low-order controller. To have a fair comparison, the same method as in HIFOO is used to find a stabilizing initial controller. The method uses a non-convex approach to minimize the maximum of the spectral abscissa of the closed-loop plant, and yields a stabilizing static output

Table 1

Comparison of optimal mixed sensitivity norms for 10 plants from Compleib

Plant Name	a_k	data-driven	<i>hinfsstruct</i>	HIFOO
AC1	10	1.90	2.30	2.38
HE1	1	1.37	1.36	1.36
HE2	10	3.08	3.36	3.55
REA2	1	3.00	2.96	2.96
DIS1	1	7.27	7.31	7.34
TG1	0.1	9.54	8.89	9.75
AGS	1	2.14	2.16	2.16
BDT2	1	9.93	9.93	9.94
MFP	1	6.08	7.23	7.17
IH	1	4.83	10.01	28.73

feedback controller K_{SOF} . In order to satisfy Condition 3 of Theorem 2, the order of Y_c is increased without changing the initial controller :

$$X_c(s) = (s + 1)^2 K_{\text{SOF}} \quad , \quad Y_c(s) = (s + 1)^2 I \quad (42)$$

The names of the chosen plants in Compleib, the design parameters and the obtained norms are shown in Table 1. For comparison, the mixed sensitivity problems are also solved for a second-order state-space controller using HIFOO and *hinfsstruct* with 10 random starts. It can be seen that the data-driven method generally achieves about the same or a lower norm. The superior results can be attributed to the fact that the controller structure is of matrix polynomial form, which has more parameters than a state-space controller of the same order.

The solver time of one iteration step depends almost linearly on the number of points used for the frequency gridding. It is also interesting to note that the controller order has a minimal impact on the solver time, making the algorithm well-suited for the design of higher-order controllers. The number of iterations until convergence mostly depends on the choice of the initial controller and a solution is generally reached in less than 25 iterations.

7 Conclusions

The frequency response of a multivariable system can be obtained through several experiments. This data can be used directly to compute a high performance controller without a parametric identification step. The main advantage is that there will be no unmodeled dynamics and that the uncertainty originating from measurement noise can be straightforwardly modeled through the weighting frequency functions. A unified convex approximation is used to convexify the H_∞ , H_2 and loop shaping control problems. Similar to the model-based approaches, this convex approximation relies on an initial stabilizing controller. Several initialization techniques are discussed and an iterative algorithm is proposed that converges to a local optimum or a saddle point of the original non-convex problem. Compared to the other frequency-domain data-driven approaches, the proposed method has a full con-

troller parametrization and also covers H_2 and loop shaping control design with a new closed-loop stability proof.
